1. Introduction

Trivalent rare earth ions, Eu(III) and Tb(III), produce red and green luminescence, respectively, when excited with ultraviolet light. However, the intensity is very weak due to their low absorption-cross section in the f→f transitions. To overcome this optical obstacle, an organic ligand is introduced in the complex system as a sensitizer. The chelating ligands strongly absorb UV light and transfers most of the absorbed energy to the rare earth ion, resulting in enhanced luminescence. The typical ligands used as sensitizers include chromophore-functionalized β-diketones. Recently, the sensitized luminescence of β-diketone-based Ln(III) complexes have been investigated intensively for their applications in light-emitting devices [1–5], as well as in sensors in environmental and biological systems [6–10]. Most β-diketone-based mononuclear Ln(III) complexes focused on the tris(β-diketone) formula, Ln[β-diketonato]3, and the ternary mixed-ligand formula, Ln[β-diketonato]3(L), using a bidentate neutral ligand, such as 1,10-phenanthroline (phen) and 2,2′-bipyridine [11]. Previously, a tetrakis(dibenzylmethano) Eu(III) complex, [Eu(DBM)4]−, was synthesized to generate strong luminescence, because solvent binding was prevented [12]. For Eu (DBM)3phen, the two different DBM and phen chromophores may complicate the energy transfer process. This study investigated which chromophore was more effective in the sensitized

The single crystal structure, luminescence and magnetic susceptibility of Cs[Ln(DBM)4] and Ln (DBM)3(phen) (Ln = Eu and Gd, DBM = dimenzoylmethanto and phen = 1,10-phenanthroine) were characterized in detail. A pentanuclear Eu(III) cluster with the formula, Eu5(DBM)10(OH)5, was obtained from Cs[Eu(DBM)4] in ethanol, while from Cs[Gd(DBM)4] in acetonitrile, a one-dimensional polymeric Gd(III) assembly with the formula, {Cs[Gd(DBM)4]}n, was achieved via a heterobimetallic backbone, composed of alternating Cs and Gd atoms bridged by DBM. Exciting the Eu(III) complexes with near-UV light produced sensitized red emission by energy transfer from the triplet excited state of DBM to the Eu(III) ion. Replacing DBM by phen increased the quantum yield from Q = 8.3% for Cs[Eu(DBM)4] to Q = 16.6% for Eu(DBM)3(phen). This was attributed to a reduction in the site-symmetry of Eu(III) from D4h to C2v. The magnetic susceptibilities of the synthesized Ln(III) complexes in the crystalline or powder states were measured using a SQUID magnetometer. The Eu(III) complexes illustrated magnetic anisotropy at low temperatures and temperature-dependent susceptibilities. The coercive field inducing the magnetic anisotropy of Eu5(DBM)10(OH)5 was more than 40-fold stronger than those of Cs[Eu(DBM)4] and Eu (DBM)3(phen). In particular, the calculation based on the Van Vleck's treatment confirmed that the thermal mixing between the excited and ground states played a key role in the temperature-dependent susceptibilities of Eu(III). The magnetic susceptibility of the Gd(III) ion in Gd(DBM)3(phen) was identical to that of the free Gd(II) ion, whereas that of the Gd(III) ion in Cs[Eu(DBM)4] was higher. The phen ligand with the π-conjugate rigid planar structure decreased the magnetic susceptibilities of the Eu(III) and Gd (III) ions.

luminescence of Eu(III) by characterizing its optical properties. Moreover, the structural and luminescent properties of [Gd(DBM)4]3+ and Gd(DBM)3(phen) were investigated. The optical properties of the chromophore to the rare earth ion may be different from those of the free chromophore because the paramagnetic metal ion increases the intersystem crossing of the chelating chromophore, resulting in a reduction of the fluorescence intensity and a subsequent increase in the phosphorescence intensity. Generally, the observed luminescence of the Gd(III) complex originates from the chromophore because the phosphorescence intensity. Generally the observed luminescence of the Gd(III) complex originates from the chromophore because the phosphorescence intensity of the Gd(III) complex is higher than the 7ππ* state of the chromophore [13,14].

Moreover, some Ln(III) ions have high electron spins and large 4f orbital moments, resulting in distinctive magnetic properties [15]. Cui et al. examined the magnetic susceptibility of six [Ln(NO3)3] complexes as a function of temperature [16]. Although Ln(III) ions were under an isostructural crystal-field, inconsistent relationships were observed between the observed magnetic properties in the series of Ln(III) ions. Manna et al. also measured the temperature dependence of the magnetic susceptibility of six binuclear Ln(III) complexes with dicarboxylate [17,18]. Antiferromagnetic interactions occurred between two adjacent Ln(III) ions with four Ln(III) ions. Although Gd(III) does not have orbital angular momentum, the Gd(III) complex exhibited super-exchange ferromagnetic properties. In particular, weak antiferromagnetic coupling between the Gd(III) ions was observed in the Ln-organic framework [18]. Therefore, the magnetic properties of Ln(III) complexes are difficult to predict, because they are quite sensitive to the ligand environment. In particular, the unquenched orbital moment of Eu(III) with the Fe3O4 ground state can give rise to fascinating magnetic properties associated with its anisotropy. Therefore, Ln(III) complexes may be applicable to the in vivo contrast imaging and luminescent probes [19–24]. To date, the magnetic properties of the Ln(III) complexes with homoleptic DBM, and mixed DBM and phen have not been reported. This paper provides details of the crystal structure, sensitizing process, and magnetic susceptibility of Eu5(DBM)10(OH)5, [Ln(DBM)4(phen)] (Ln=Eu and Gd).

2. Experimental section

2.1. Synthesis and composition analysis

EuCl3·6H2O (99%), GdCl3·6H2O (99%), dibenzoylmethane (DBMH) (99%), and 1,10-phenanthroline (99%) were purchased from Aldrich. The organic solvents were obtained from Samchun. All chemicals were used without further purification.

Elementary analysis (EA) of the carbon, hydrogen and nitrogen contents was performed using a CE EA-1110 elemental analyzer. The cations were analyzed quantitatively with an Optima 7100 inductively coupled plasma (ICP) atomic emission spectrometer. Complexes of Cs[Ln(DBM)4] (Ln=Ed and Gd) were synthesized using a method described elsewhere [12]. For [Ln(DBM)3(phen)] (Ln=Ed and Gd), 3 mmol of DBMH in 5 mL of ethanol was added to a solution of 1 mmol of LnCl3·6H2O and 1 mmol of phen in a 1:1 water-ethanol mixed solvent (20 mL). After adjusting the pH of the solution between 7–7.5 with dilute CsOH solution, the resulting solution was stirred for 2 h at room temperature. After filtering and washing several times with water and ethanol, alternately, the precipitate was dried in an electric oven.

3. Results and discussion

3.1. Crystal structure

The Eu₅(DBM)₁₀(OH)₅ complex crystallized in the monoclinic space P2₁/c. As shown in Fig. 1, the single crystals, which were grown from an ethanol solution of tetrakis(dibenzylmethano) Eu(III), formed a pentanuclear Eu₅ polyhedron with the formula, Eu₅(μ₄-OH)(μ₃-OH)₄(μ-DBM)₄(DBM)₆. Previously, the pentanuclear Ln₅ complexes were obtained by a reaction in the presence of N-methylmorpholine [27] or triethylamine [28–30]. On the other hand, in the absence of amines or catalysts, the cesium ion could play a key role in the deprotonation of ethanol, resulting in the decomposition of DBM (Scheme 1). Table S2 lists the selected bond lengths and angles. As shown in Fig. 1, each Eu atom was coordinated to eight oxygen atoms, adopting a square antiprism geometry.

The Cs[Gd(DBM)₄] complex crystallized in the monoclinic space group, C2/c, and the complete molecule was generated by the site symmetry of a crystallographic two-fold rotation axis. As shown in Fig. 2, the complex formed a one-dimensional supramolecular polymer in the crystalline state, which was composed of alternating Gd and Cs that were bridged by the DBM ligands. Gd atoms also achieve 8-coordination by the eight oxygen atoms from the four DBM ligands. As listed in Table S3, the Gd–O bond distances ranged from 2.340(19) to 2.409(2) Å. These distances were more than 0.10 Å longer than Ln–O in Ln(DBM)₃·H₂O (Ln=Ho and Yb) [31,32].

For [Ln(DBM)₃(phen)] (Ln=Eu and Gd), the complexes crystallized in the monoclinic space group P2₁/c and the triclinic space group P-1, respectively. Fig. S1 shows a perspective view of the Eu(III) crystalline form. Tables S4 and S5 list the selected bond lengths and bond angles of the two complexes. The central Ln(III) ion is coordinated by six oxygen atoms from three DBM ligands and two nitrogen atoms from phen. The bond lengths and bond angles formed by the central Ln atom are comparable to those reported elsewhere [32]. Eight-coordinated polyhedrons most frequently form dodecahedrons or square antiprisms [33]. The square antiprism geometry can be accessed by the two rectangular and six triangular faces. The calculated locations of the N and O atoms were displaced from their mean planes by less than 0.04 Å for the Eu(III) crystals and 0.10 Å for the Gd(III) crystals. The displacement of each atom from the mean plane indicates that the Ln(III) complex forms a slightly distorted square antiprism polyhedron.

3.2. Sensitized luminescence and quantum yield

3.2.1. Luminescence and excitation spectra

The absorption spectra of the free ligands, DBMH and phen, and two Eu(III) complexes were measured in a methanol solution. As shown in Fig. S2, the DBM ligand and [Eu(DBM)₄]⁺ complex produced two apparent absorption bands at ~350 nm as the main peak and ~250 nm as the minor (hereafter referred to as A- and B-bands, respectively, in order of increasing energy). Table S6 lists the resolution of the electronic absorption band using a Gaussian formula. A comparison of the peak positions and the relative intensities of the observed bands between the complex and ligands confirmed that the A-band and C-band (λmax = 227 nm) of the complex were assigned to the π-π* transitions of DBM and phen, respectively, and the B-band was a combination of the B-band of DBM and the A-band of phen.

Fig. 3 shows the emission and excitation spectra of Eu₅(DBM)₁₀(OH)₅ in the crystalline state and Cs[Eu(DBM)₄] in the powdered state, which were measured at room temperature. When excited at 398 nm, both produced typical luminescence features in the 570–720 nm region, arising from the 5D₀→7F_j (j=0–4) transitions of Eu(III). A very strong and narrow luminescence band at 612.8 nm, which was labeled as hypersensitive, resulted from the 5D₀→7F₂ transition of Eu(III).
Fig. 4. (a) Calibrated emission spectra of [Eu(DBM)₃(phen)] (1) and Cs[Eu(DBM)₄] (2) (λₑm=405 nm), and (b) excitation spectrum of [Eu(DBM)₃(phen)] (λₑm=612 nm) measured at room temperature.

Significant spectral differences in this hypersensitive band between the two complexes can be found in the intensity and band structure. For [Eu(DBM)₄]⁻, the band shape was a singlet and its intensity was more than 20 times stronger than that of Eu(DBM)₃(OH)₃ with a triplet band structure. A series of weak bands at 394, 465 and 526 nm, corresponding to the Eu(III) direct transitions, were superimposed on the broad band. Additional excitation bands, which appeared in the 500–600 nm range (inserted in Fig. 4(b)), corresponded to the transitions from the 1F₁ and 1F₂ states to the ⁵D₀ state. The broad band, peaking at 405 nm, was the result of energy transfer from DBM to Eu(III). For Eu(DBM)₃(5-amino-phen) covalently assembled on a functionalized silica surface, the emission intensity between the ⁵D₀ → ⁷F₃ transitions was found to vary upon the excitation wavelength of the energy transfer band [34,35]. For most of the europium complexes with phen the energy transfer from phen to Eu(III) appeared in the 250–380 nm excitation region. These results suggest that the excitation process via DBM was more effective than that via phen. Any optical processes of phen in the complex are suppressed entirely by DBM within Eu(DBM)₃(phen). This could be because the energy gap between the ππ* donating level of DBM and the emitting ⁵D₀ level of Eu(III) is smaller than the case resulting from phen: ΔEgap = 7450 cm⁻¹ for DBM and ΔEgap = 11170 cm⁻¹ for phen. The PL and excitation spectra of [Gd(DBM)₄]⁻ and [Gd(DBM)₃(phen)] were also measured to assess the role of the two chromophores in the sensitized luminescence of Eu(III) in Eu(DBM)₃(phen). The spectral features of the PL and the excitation spectra of [Gd(DBM)₃(phen)] were similar to those of [Gd(DBM)₄]⁻. The 325-nm excitation produced bell-type emission from both, peaking at 502 nm, and its excitation peaked at 405 nm (Fig. S3). The spectra were resolved to three Gaussian components, peaking at 611.5 nm emission from Eu(DBM)₃(phen) complex was similar to that of [Eu(DBM)₄]⁻. A series of weak bands at 394, 465 and 526 nm, corresponding to the Eu(III) direct transitions, was superimposed on the broad band. Additional excitation bands, which appeared in the 500–600 nm range (inserted in Fig. 4(b)), corresponded to the transitions from the 1F₁ and 1F₂ states to the ⁵D₀ state. The broad band, peaking at 405 nm, was the result of energy transfer from DBM to Eu(III). For Eu(DBM)₃(5-amino-phen) covalently assembled on a functionalized silica surface, the relative emission intensity between the ⁵D₀ → ⁷F₃ transitions was found to vary upon the excitation wavelength of the energy transfer band [34,35]. For most of the europium complexes with phen the energy transfer from phen to Eu(III) appeared in the 250–380 nm excitation region. These results suggest that the excitation process via DBM was more effective than that via phen. Any optical processes of phen in the complex are suppressed entirely by DBM within Eu(DBM)₃(phen). This could be because the energy gap between the ππ* donating level of DBM and the emitting ⁵D₀ level of Eu(III) is smaller than the case resulting from phen: ΔEgap = 7450 cm⁻¹ for DBM and ΔEgap = 11170 cm⁻¹ for phen. The PL and excitation spectra of [Gd(DBM)₄]⁻ and [Gd(DBM)₃(phen)] were also measured to assess the role of the two chromophores in the sensitized luminescence of Eu(III) in Eu(DBM)₃(phen). The spectral features of the PL and the excitation spectra of [Gd(DBM)₃(phen)] were similar to those of [Gd(DBM)₄]⁻. The 325-nm excitation produced bell-type emission from both, peaking at 502 nm, and its excitation peaked at 405 nm (Fig. S3). The spectra were resolved to three Gaussian components, peaking at 611.5 nm emission from Eu(DBM)₃(phen) complex was similar to that of [Eu(DBM)₄]⁻. The excitation spectrum of [Eu(DBM)₃(phen)] and [Gd(DBM)₄]⁻ are similar to the energy-transfer band of Eu(DBM)₃(phen).

compared to [Eu(DBM)₄]⁻. For the hypersensitive emission, the Eu(DBM)₃(phen) complex produced three lines, whereas the [Eu(DBM)₄]⁻ complex produced only a single line. Assuming that [Eu(DBM)₄]⁻ is isostructural with [Gd(DBM)₄]⁻, the site symmetry of Eu in [Eu(DBM)₄]⁻ surrounded by eight equivalent O atoms is Dₘ₆, and that of Eu in Eu(DBM)₃(phen) surrounded by two N and six O atoms is C₂ᵥ. (Figs. 2 and S1). Taking into account selection rules for the ⁵D₀ → ⁷F₃ (J=0–4) transitions of Eu(III) in the Dₘ₆ and C₂ᵥ symmetries (Table S7), the number of lines observed in the hypersensitive band well reflects the effects of the site symmetry of Eu(III) on the band structure. Unlike other ⁵D₀ → ⁷F₃ transitions, the ⁵D₀ → ⁷F₁ transition for most of Eu(III) complexes is allowed by the magnetic dipole moment. Therefore, this transition well reflects the site symmetry of the Eu(III) ion in the number of lines and its intensity is almost independent of the environment with moderate intensity, as shown in Fig. 4(a): two lines for [Eu(DBM)₄]⁻ and three lines for Eu(DBM)₃(phen). The excitation spectrum of the 611.5-nm emission from Eu(DBM)₃(phen) complex was similar to that of [Eu(DBM)₄]⁻. A series of weak bands at 394, 465 and 526 nm, corresponding to the Eu(III) direct transitions, was superimposed on the broad band. Additional excitation bands, which appeared in the 500–600 nm range (inserted in Fig. 4(b)), corresponded to the transitions from the ⁵F₁ and ⁵F₂ states to the ⁵D₀ state. The broad band, peaking at 405 nm, was the result of energy transfer from DBM to Eu(III). For Eu(DBM)₃(5-amino-phen) covalently assembled on a functionalized silica surface, the relative emission intensity between the ⁵D₀ → ⁷F₁ and ⁵D₀ → ⁷F₂ transitions was found to vary upon the excitation wavelength of the energy transfer band [34,35]. For most of the europium complexes with phen the energy transfer from phen to Eu(III) appeared in the 250–380 nm excitation region. These results suggest that the excitation process via DBM was more effective than that via phen. Any optical processes of phen in the complex are suppressed entirely by DBM within Eu(DBM)₃(phen). This could be because the energy gap between the ππ* donating level of DBM and the emitting ⁵D₀ level of Eu(III) is smaller than the case resulting from phen: ΔEgap = 7450 cm⁻¹ for DBM and ΔEgap = 11170 cm⁻¹ for phen. The PL and excitation spectra of [Gd(DBM)₄]⁻ and [Gd(DBM)₃(phen)] were also measured to assess the role of the two chromophores in the sensitized luminescence of Eu(III) in Eu(DBM)₃(phen). The spectral features of the PL and the excitation of Gd(DBM)₃(phen) are similar to those of [Gd(DBM)₄]⁻. The 325-nm excitation produced bell-type emission from both, peaking at 502 nm, and its excitation peaked at 405 nm (Fig. S3). The spectra were resolved to three Gaussian components, peaking at 440, 489 and 542 nm. Taking the mirror image and the Stokes shift into consideration, the ⁵D₀ → ⁷F₂ transitions of Eu(III) in Eu(DBM)₃(phen) were similar to the transitions of Gd(DBM)₃(phen) are similar to those of [Gd(DBM)₄]⁻. The PL and excitation spectra of [Gd(DBM)₄]⁻ and [Gd(DBM)₃(phen)] were also measured to assess the role of the two chromophores in the sensitized luminescence of Eu(III) in Eu(DBM)₃(phen). The spectral features of the PL and the excitation of Gd(DBM)₃(phen) are similar to those of [Gd(DBM)₄]⁻. The 325-nm excitation produced bell-type emission from both, peaking at 502 nm, and its excitation peaked at 405 nm (Fig. S3). The spectra were resolved to three Gaussian components, peaking at 440, 489 and 542 nm. Taking the mirror image and the Stokes shift into consideration, the ⁵D₀ → ⁷F₂ transitions of Eu(III) in Eu(DBM)₃(phen) were similar to the transitions of Gd(DBM)₃(phen) are similar to those of [Gd(DBM)₄]⁻. The PL and excitation spectra of [Gd(DBM)₄]⁻ and [Gd(DBM)₃(phen)] were also measured to assess the role of the two chromophores in the sensitized luminescence of Eu(III) in Eu(DBM)₃(phen). The spectral features of the PL and the excitation of Gd(DBM)₃(phen) are similar to those of [Gd(DBM)₄]⁻. The 325-nm excitation produced bell-type emission from both, peaking at 502 nm, and its excitation peaked at 405 nm (Fig. S3). The spectra were resolved to three Gaussian components, peaking at 440, 489 and 542 nm. Taking the mirror image and the Stokes shift into consideration, the ⁵D₀ → ⁷F₂ transitions of Eu(III) in Eu(DBM)₃(phen) were similar to the transitions of Gd(DBM)₃(phen) are similar to those of [Gd(DBM)₄]⁻.
of the site symmetry of Eu(III) plays a key role in determining the luminescence efficiency, particularly depending on the extent to which the (2J+1) degeneracy of $^7F_J$ is removed. For Eu(III) in the Cs[Eu(DBM)$_4$]$_4$ complex, the hypersensitive band consists of only a single transition from the $A_g$ level to the $E_g$ level, whereas for the Eu(DBM)$_3$(phen) complex, the hypersensitive band consists of the three transitions from the $A_1$ level ($^5D_0$) to the $A_2$, $B_1$, and $B_2$ levels ($^7F_2$).

3.2.2. Quantum yield

The luminescence lifetime and the absolute sensitized-luminescence quantum yield of the Eu(III) complexes prepared in powder were determined precisely at room temperature. As listed in Table 1, no significant difference in the lifetime was observed between the two complexes, while the quantum yield of Eu(DBM)$_3$(phen) ($Q_{sen}=0.17$) was 2 times larger than that of Cs[Eu(DBM)$_4$]$_4$ ($Q_{sen}=0.083$). Note that the absorption coefficients of Cs[Eu(DBM)$_4$]$_4$ and Eu(DBM)$_3$(phen) were calculated to be 0.96 and 0.79, respectively. The observed quantum yield of the sensitized luminescence of the Eu(III) complexes, $Q_{sen}$, is associated with the efficiency of the energy transfer from the ligand to europium ($\eta_{ET}$), and radiative and nonradiative processes ($Q_{eff}$) occurring from the receiving levels to the $^7F_0$ ground state as $Q_{sen}=\eta_{ET} \times Q_{eff}$. The term of $Q_{sen}$ has been estimated using the observed luminescence lifetime, $\tau_{obs}$, and the natural lifetime, $\tau_0$, using $Q_{sen}=\tau_0/\tau_{obs}$. The natural lifetime, which is responsible for the $^5D_0\to^7F_0$ transition, could not be measured directly because of its faint or forbidden intensities. Werstet et al. reported the estimation of $\tau_0$ from the shape of the corrected emission spectrum, using the formula [36].

$$\frac{1}{\tau_0}=A_{MD,0}R^3 \left( \frac{I_{tot}}{I_{MD}} \right)$$

where the MD-allowed probability of the $^5D_0\to^7F_0$ transition, $A_{MD,0}$, is a constant as 14.65 s$^{-1}$ and the refractive index, $n$, was assumed to 1.5 for a solid sample. The term, $(I_{tot}/I_{MD})$, was the ratio of the total area of the observed emission. Using these approximations, $Q_{sen}$ and $\eta_{ET}$ were calculated for the two Eu(III) complexes. As listed in Table 1, the energy-transfer efficiency from DBM to Eu(III) in Eu(DBM)$_3$(phen) was ~ two times larger than that in Cs[Eu(DBM)$_4$]$_4$. This shows that the site symmetry of Eu(III) plays a key role in determining the luminescence efficiency, particularly depending on the extent to which the (2J+1) degeneracy of $^7F_J$ is removed. For Eu(III) in the Cs[Eu(DBM)$_4$]$_4$ complex, the hypersensitive band consists of only a single transition from the $A_g$ level to the $E_g$ level, whereas for the Eu(DBM)$_3$(phen) complex, the hypersensitive band consists of the three transitions from the $A_1$ level ($^5D_0$) to the $A_2$, $B_1$, and $B_2$ levels ($^7F_2$).

3.3. Magnetic properties

3.3.1. Eu(III) complex

The ZFC and FC molar susceptibilities of the three Eu(III) complexes were measured over the temperature range of 5–300 K. For Eu(DBM)$_3$(OH)$_5$, the temperature dependence of $\chi_{M,ZFC}$ was anomalous (Fig. 5(a)). Four distinctive steps were observed in the temperature ranges, 5–11 K, 11–225 K, 225–259 K, and 259–300 K. At $T=5$ K, $\chi_{M,ZFC}$ was $190 \times 10^{-4}$ emu mol$^{-1}$. With increasing temperature, $\chi_{M,ZFC}$ increased, rapidly in the first step and gradually in the second step. In the third step, the increase in $\chi_{M,ZFC}$ escalated but slowed down gradually. At $T=257$ K, $\chi_{M,ZFC}$ reached a maximum (3.47 emu mol$^{-1}$), corresponding to the block temperature ($T_B$). Above this temperature, $\chi_{M,ZFC}$ decreased gradually with increasing...
temperature. Upon subsequent cooling from 300 to 259 K, the $\chi_{M,FC}$ values were identical to those of $\chi_{M,ZFC}$. Below $T = 259$ K, $\chi_{M,FC}$ increased gradually with decreasing temperature and showed irreversibility with regard to $\chi_{M,ZFC}$. The difference between $\chi_{M,FC}$ and $\chi_{M,ZFC}$ below $T_0$ resulted mainly from the existence of energy barriers of magnetic anisotropy. During the ZFC process, the spins were locked in random directions for the Eu(III) complexes. At $T = 5$ K, the applied magnetic field ($H_{app} = 1000$ Oe) was insufficient to rotate the spins in the direction of the applied field, resulting in low susceptibility. The observed $\chi_{M,ZFC}$ reflected only the contribution of the particles that overcame the energy barriers specified as the coercive field strength, $H_c$. Using the relationship between $\chi_{M,FC}$ and $\chi_{M,ZFC}$ (Eqs. (51) and (52)) [37], $H_c$ was calculated from the observed ZFC and FC molar susceptibilities. As shown in Fig. 5(a), at $T = 5$ K, the coercive field strength reached more than 3500 Oe, which is much stronger than the applied magnetic field. These results showed that the magnetic anisotropy of the Eu(III) ion in Eu$_2$(DBM)$_{10}$(OH)$_5$ was effective in inducing the single-molecule magnet properties below $T = 257$ K. In addition, the field dependence of magnetization of Eu$_2$(DBM)$_{10}$(OH)$_5$ was measured at 2, 5, 77, and 300 K. Fig. S4 shows uncorrected molar magnetization of Eu$_2$(DBM)$_{10}$(OH)$_5$ measured at $T = 2$ K. The negative magnetization was observed for Eu$_2$(DBM)$_{10}$(OH)$_5$ at the four temperatures. This might be because in Eu$_2$(DBM)$_{10}$(OH)$_5$, the demagnetization of the ligands ($\chi_{M} = -1.44 \times 10^{-3}$ emu mol$^{-1}$) is greater than the magnetization of Eu(III) ($\chi_{M,ZFC} = 1.90 \times 10^{-4}$ emu mol$^{-1}$ at 5 K). For Cs[Eu(DBM)$_4$] and Eu(DBM)$_3$(phen), the magnetic anisotropy in the ZFC and FC molar susceptibilities were negligible (Fig. 5(b) and (c)) above $T = 80$ K. On the other hand, the calculated $H_c$ values were very low, even at low temperatures ($\leq 60$ Oe), so that the hysteresis symptom did not appear in the field dependence of molar magnetization even at low temperatures.

For Eu(III) and Sm(III), the energy interval, $\Delta E_f$, between two consecutive $J$ and $J-1$ states, are not very great compared to $kT$ (0.689 T cm$^{-1}$). Van Vleck predicted that for Eu(III) and Sm(III), the splitting of the excited states by a surrounding crystal field and the thermal population of the crystal-field levels caused a second-order contribution to the magnetic susceptibility [38]. Using Eq. (53) with $\mu_B = 9.27 \times 10^{-21}$ emu for the free atom, the molar susceptibility of the three Eu(III) complexes was calculated and compared with the observed $\chi_{M,FC}$ values. As shown in Fig. S5, the values observed for Eu(DBM)$_3$(phen) were quite close to the theoretical values. Those of Eu$_2$(DBM)$_{10}$(OH)$_5$, however, were considerably lower than the calculated ones. This suggested that the distortion by interatomic forces in the Eu$_2$(DBM)$_{10}$(OH)$_5$ complex could be significant. Therefore, the atomic permanent moment ($\mu_p = 9.27 \times 10^{-21}$ emu) was not valuable for the Eu(III) complex. The phenomenological temperature-dependent effective Bohr magnetic moment was considered to be a second-order correction. By replacing $\mu_p$ with $\mu_{eff}$ in Eq. (53), the experimental $\mu_{eff}$ was determined by fitting the observed $\chi_{M,FC}$. As listed in Table 2, the experimental $\mu_{eff}$ of Eu$_2$(DBM)$_{10}$(OH)$_5$ varied from 2.08 $\times 10^{-21}$ emu (300 K) to 2.38 $\times 10^{-21}$ emu (5 K). These values were less than 1/4, compared to the permanent moment $\mu_p$. For Cs[Eu(DBM)$_4$] and Eu(DBM)$_3$(phen), the experimental $\mu_{eff}$ values were close to $\mu_p$. These results showed that the interatomic-force distortion was negligible for these two complexes.

3.3.2. Gd(III) complexes

The ZFC and the FC molar susceptibilities of the Cs[Gd(DBM)$_4$] and Gd(DBM)$_3$(phen) complexes were also measured over the temperature range, 5–300 K. No magnetic anisotropy was observed for the Gd(III) complexes, because $\chi_{M,FC}$ and $\chi_{M,ZFC}$ were identical at a given temperature. As shown in Fig. 6(a), the Cs[Gd(DBM)$_4$] complex is strongly paramagnetic, and $\chi_{M,T}$ was temperature-independent. The experimentally determined $\chi_{M,T}$ value was 10.42 emu K mol$^{-1}$ ($\sigma = \pm 0.07$) over the observed temperature range. According to the free-ion approximation of the Gd(III) ion, the theoretical value of $\chi_{M,T}$ for the $^{5}S_{7/2}$ ($S = 7/2$, $L = 0$, $J = 7/2$) ground state was calculated to be 7.88 emu mol$^{-1}$. The observed $\chi_{M,T}$ value at $H_{app} = 1000$ Oe was slightly higher than the value of the Gd(III) free-ion state. A plot of $1/\chi_M$ versus $T$ obeyed the Curie–Weiss law (Fig. S6). The Curie constant and Weiss temperature were determined to be $C = 10.45$ emu K mol$^{-1}$ and $\Theta = 0.88$ K, respectively. The magnetic-field dependence of the magnetization of Cs[Gd(DBM)$_4$] was measured at 2, 5, 77, and 300 K. As shown in Fig. 6(b), at $T = 2$ K, with increasing magnetic field, the relative molar magnetization, $M/M_{sat}$, of the Gd(III) complex increased and became saturated at a high field ($M_{sat} = 52400$ emu). The magnetic-field dependences of the molar magnetization of the Gd(III) complexes at $T = 2$ and 5 K were fitted using the Brillouin function. The best fitting resulted in $g_{eff} = 2$ and $\mu_{eff} = 9.27 \times 10^{-21}$ emu. These results showed that the overall magnetic properties of the Gd(III) ion in the complex were identical to those of the Gd(III) free ion with $g_{eff} = 2$. The observed magnetic properties of the Gd(DBM)$_3$(phen) complex are comparable to those of the Cs[Gd(DBM)$_4$] complex (Figs. S7 and S8). The value of $\chi_{M,T}$ obtained was 7.41 emu mol$^{-1}$ over the 5–300 K range and the Curie–Weiss fitting resulted in $C = 7.44$ emu K mol$^{-1}$ and $\Theta = 0.14$ K. The observed $\chi_{M,T}$ of the Gd(III) ion in Gd(DBM)$_3$(phen) was slightly lower than that of the free Gd(III) ion. For the magnetization of lanthanide ions the ligand phen with a π-conjugate rigid planar structure may be less effective than DBM with two phenyl terminal groups.

4. Conclusions

An ethanol solution of Cs[Eu(DBM)$_4$] yielded a pentanuclear europium cluster with the composition Eu$_2$(μ$_3$-OH)[μ$_2$-OH]$_2$(μ$_2$-DBM)$_3$(DBM)$_4$. The cluster produced a hypersensitive red emission via energy transfer from DBM to Eu(III). On the other hand, the emission intensity of the cluster was markedly weaker than those of Cs[Eu(DBM)$_4$] and Eu(DBM)$_3$(phen), because of OH quenching. An acetone solution of Cs[Gd(DBM)$_4$] yielded a one-dimensional polymeric assembly. The molar susceptibilities of Cs[Gd(DBM)$_4$] were slightly larger than that of Gd(DBM)$_3$(phen). The ligand phen with a π-conjugate planar structure may be less effective than DBM in the magnetization of lanthanide ions.
